After the intensive years 1981 and 1982, minimal effort was expended on Lake Ontario in 1983 to allow an intensive surveillance program to be conducted in 1984. As indicated in the Lakes International Surveillance Data Report, only two chemical cruises were conducted in 1983 (June 14-15 and June 24-25). The 1983 cruise data is shown in Table 1 and is summarized in Table 2. The 1983 cruise data is summarized in Table 2. The 1983 cruise data is summarized in Table 2. The 1983 cruise data is summarized in Table 2.

Data from these cruises were used to report any instances of negative trends and to update trend analysis of temperature and nitrogen, barium concentrations. When compared with data from other cruises conducted in a given year, these data were found to be representative of the entire water column. Therefore, trend studies from 1981 to 1983 were based on surface concentrations. Statistical analysis of the data was conducted using the Student's t-test. The data were analyzed using the Student's t-test. The data were analyzed using the Student's t-test.

REPORT ON STATUS OF OPEN WATERS OF LAKE ONTARIO - 1984-

M. Neilson and R.J.J. Stevens

Statistical analysis of data from years 1977, 1981, 1982, and 1983 was done to reduce these errors. The statistical analysis of the data from 1977 has been maintained for this report.

After the intensive years, 1981 and 1982, minimal effort was expended on Lake Ontario in 1983 to allow an in-depth surveillance program to be conducted on Lake Superior, as identified in the Great Lakes International Surveillance Plan (GLISP). Only two full chemistry cruises were conducted on Lake Ontario: March 14-18 (8322001) and April 5-8 (8322004). The 94 stations shown in Figure 1 were sampled as outlined in Table 1. Physical parameters, as well as the less stable nutrients filtered nitrate-plus-nitrite, filtered ammonia and soluble reactive phosphorus, were analyzed onboard ship at the time of collection. The remaining parameters were returned to the National Water Quality Laboratory in Burlington for analysis.

Data from these cruises were used to report any incidents of objective noncompliance and to update trend analysis of phosphorus and nitrogen. Surface concentrations, when compared with mean whole water column concentrations in a paired t-test, have been found to be representative of the entire water column (report in progress). Therefore, trend studies from 1970 to 1983 were based solely on spring surface concentrations. Statistical analysis involved the use of both collected surface data and area-weighted means. The latter values were calculated using the computer program ALDAR (Neilson et al. 1984) and the 17 zones illustrated in Figure 2.¹

Data have been graphically presented using the "box plot" (McGill et al. 1978). The median for each year is represented by a dashed line within each box. The upper and lower quartiles of the data set define the positions of the upper and lower edges of the box, while the width of the box is proportional to the square root of the sample size ($\sqrt{N}$, where N is the number of samples). The highest and lowest spring surface values are represented by short horizontal lines on the graph.

¹ Statistical analysis of data from years 1977, 1981 and 1982 has been done to redefine these zones. The write-up and computer programming of these new zones has yet to be completed. Therefore, the same zones used since 1977 have been maintained for this report.

A third cruise was conducted October 3 - 7 (8322044) with the express purpose of verifying the 0.65 conversion factor for specific conductance to total dissolved solids. A summary of the results will be given in this report.

Phosphorus

Figure 3 shows the yearly trend in lakewide spring mean total phosphorus concentrations. Values were area-weighted to compensate for station density throughout the lake. Linear regression analysis described this trend according to the equation

$$y = -0.0010x + 0.0277 \quad (r = 0.94)$$

i.e., a rate of decrease of $1.0 \text{ ug PL}^{-1}\text{yr}^{-1}$. If this rate equation can be used as a predictive tool, by 1986 total phosphorus levels in the open waters of Lake Ontario will have achieved the 10.0 ugL^{-1} objective proposed by the Great Lakes Research Advisory Board (July, 1978).

When the t-test was applied to the spring surface total phosphorus raw data for the years 1982 and 1983, a decrease of 8.7% (1.3 ugPL^{-1}) was found and the means were significantly different ($p > 0.05$). The test was reapplied to the data using only similar stations for the 2 years and, although only an 1.2 ugPL^{-1} change was noted (8.0%), the decrease was still found to be significant (see Table 2). Note that the actual decrease reported agrees well with the general trend seen in phosphorus levels.

Box plots of spring surface total phosphorus for the period 1970-1983 (shown in Figure 4) demonstrated that 1983 had the lowest median value recorded to date (12.6 ugPL^{-1}). However, ice cover, which was experienced over the northeast section of the lake during the spring sampling period in 1982, could have biased the median value for that year. During 1982, ice cover prohibited sampling of all stations in zone 1 during the first spring cruise, and half the stations in zone 1 during the second spring cruise. Table 3 lists the area-weighted surface total phosphorus concentration in each zone, averaged over the two 1983 spring cruises. As zone 1 reported the lowest mean concentration, the data from these stations are undoubtedly included in the minimum-to-low-quartile range of the box plot (i.e. lower 25% of the data) and were instrumental in lowering the 1983 median.

As is demonstrated both by the box plots (Figure 4) and the coefficients of variability (Table 2), even when the full component of stations sampled in 1983 are considered, the variability of the data in 1983 was less than that seen in 1982. This seems to indicate that, at this time, nearshore inputs had localized impact resulting in generally uniform lakewide conditions. The surface plots of total phosphorus for the two Spring cruises (Figures 5, 6) illustrate the nearshore inputs and their zones of impact. On the first cruise (8322001) these included Oshawa (zone 5), Toronto (zone 6), the Welland Canal (zone 9) and Black River Bay (zone 16). On the second cruise (8322004) the major areas of impact were the Welland Canal and Black River Bay, and, to a lesser extent, Oswego (zone 14), Rochester (zone 12) and Hamilton (zone 7). On both cruises, however, these inputs remained fairly localized and did not affect the mid-lake zones 10 and 17.

Linear regression analysis of raw spring surface soluble reactive phosphorus (SRP) data indicated a constant rate of decrease of $0.85 \text{ ugPL}^{-1} \text{ yr}^{-1}$ since 1970 ($r = 0.73$). A comparison of 1982 and 1983 SRP data substantiated this rate change. T-test analysis of spring surface results for the two years, both when applied to all stations and only similar stations sampled, reported a significant ($\alpha = 0.05$) decrease of 19.2% (8.5 ugPL^{-1}) and 21.3% (9.5 ugPL^{-1}), respectively (Table 2). The 1983 median SRP value (3.4 ugPL^{-1}), similar to total phosphorus, was the lowest reported in 14 years. Unlike total phosphorus, however, there was an increase in variability relative to 1982 as illustrated by the coefficients of variability in Table 2.

Surface plots of SRP during the two spring cruises are shown in Figures 7 and 8. Note that the contour lines seem to follow the bathymetry of the lake, there being no remarkable nearshore inputs. On both cruises a nearshore-offshore concentration gradient existed wherein midlake (deep) stations reported higher levels of SRP. Similarly, lowest concentrations were found in the shallow zone 1 region of the lake.

Nitrogen

In 1983, the area-weighted mean surface ($\text{NO}_3 + \text{NO}_2$) concentration of 356.0 ugNL^{-1} for the whole lake during spring (isothermal) conditions represented a 0.1 ugNL^{-1} decrease from that of 1982. When a t-test was performed on all the 1m raw data from the 2 years, the means were found to be significantly different at the 95% confidence level (Table 2). It is interesting to note that in the zones along the northern and western shores a ($\text{NO}_3 + \text{NO}_2$) decrease relative to 1982 was found, while zones 10, 11, 12, 13, 14 and 17 (central and southern Lake Ontario) showed an increase. Recall that, during the 1982 spring cruises, ice cover prohibited most of the sampling of stations in zone 1. The levels of ($\text{NO}_3 + \text{NO}_2$) in this zone during 1983 were among the lowest found throughout the lake (see Appendix 1). Inclusion of the data collected at these stations undoubtedly lowered the

1983 mean concentration. The t-test, therefore, was rerun using only stations sampled during both years. There was then found to be no significant difference between the 2 years ($\alpha = 0.05$).

Although there was no change seen in ($\text{NO}_3 + \text{NO}_2$) concentrations from 1982 to 1983, linear regression analysis of the spring surface raw data from 1970 to 1983 indicated a significant rate of increase of $8.3 \text{ ugNL}^{-1}\text{yr}^{-1}$, or 14000 metric tons/year. Stevens et al. (in press), assuming a similar constant rate of increase of nitrogen, calculated an annual loading of 15000 metric tons per year ($5.4 \text{ ugNL}^{-1}\text{yr}^{-1}$) to Lake Huron. As the volume of Lake Huron: Lake Ontario is approximately 2:1 (Robertson and Jordan 1978), and the rate of change in concentration in Lake Ontario is almost twice that of Lake Huron, the two lakes appear to be responding in a similar manner.

The box plots of spring surface nitrate-plus-nitrite, shown in Figure 9, show an increase in variability for the 1983 results. Whereas, in 1982, 50% of the values were within a 21 ugL^{-1} range, in 1983 the upper and lower quartile differed by 43 ugL^{-1} . As the (median - lower quartile) difference was far greater for 1983 (0.028 compared to 0.012 ugL^{-1}), much of the increased variability can be explained by inclusion of the lower values found at stations in zone 1. When only similar stations were considered, the variability in 1983 decreased considerably. (see Table 2).

A west-east midlake transect was chosen and depth-concentration profiles were made at each station in the transect to investigate any trans-lake (spatial) trend (see Figures 10, 11). On both cruises, levels in the western end and midlake were very similar, while the eastern end of the lake showed lower concentrations.

Total Dissolved Solids

In the 1978 Great Lakes Water Quality Agreement, the objective for total dissolved solids (TDS) in Lake Ontario is 200 mgL^{-1} . However, as TDS analysis is such a time-consuming procedure, specific conductance has instead been used to estimate TDS according to the formula:

$$\text{TDS} = \text{SC}_{25} \times 0.65 (\pm 0.01) \quad (1a)$$

where SC_{25} is the specific conductance measured at 25°C . Spring surface total dissolved solids levels, as calculated from equation 1a, have been reported in excess of the IJC objective throughout the lake since 1976 (IJC Annual Report, 1976). Likewise in 1983, with the exception of Black Bay stations 76 and 97 (zone 16) on both cruises, and the stations in zone 9 (Niagara River) during cruise 8322004, the calculated TDS levels were all in excess of 200 mgL^{-1} (18/188 surface measurements were $> 200 \text{ mgL}^{-1}$).

On the 1983 October cruise (8322044), 1 litre samples were collected from the 1 m depth at 60 stations in Lake Ontario for total dissolved solids analysis. Only 3 of the 60 reported TDS values were above 200 mgL^{-1} (see Table 4). In contrast, when the conductivity values from this cruise were converted to TDS using equation 1a, 44 of the 60 stations showed TDS levels at or above the objective. Table 4 gives, for each station, the $\text{TDS}/\text{SC}_{25}$ ratio. It appears, from this set of data, that a more exact conversion factor would be 0.58, ie.

$$\text{TDS} = \text{SC}_{25} \times 0.58 (\pm 0.03) \quad (1b)$$

Applying equation 1b to the spring conductivity values, only 41/94 stations on cruise 8322001 and 5/94 stations on cruise 8322004 exceeded the 200 mgL^{-1} objective. Perhaps the continually-reported objective noncompliance has been reflectant of the conversion factor rather than the state of the lake. It is recommended that this comparative study be repeated during the 1984 spring cruises.

Final data appeared suspect. Therefore, conductance (S.C.) was calculated according to the equation

$$S.C. = 2.60(Ca) + 3.82(Mg) + 2.13(Na) + 1.84(K) + 2.14(Cl) + 0.864(Alk) + 1.54(SO_4)$$

Ice cover prohibited sampling in these zones.
